Overview

- Group velocity dispersion in single mode fibers, where different spectral components of a pulse travel at slightly different group velocities. This causes pulse broadening that limits the fiber bandwidth.

Key Takeaways

Single-mode fibers primarily exhibit intramodal (chromatic) dispersion, which includes material and waveguide dispersion.

Overview of Dispersion in Single-Mode Fibers

Unlike multimode fibers, single-mode fibers do not experience intermodal dispersion because only the fundamental mode propagates through the fiber. However, pulse broadening still occurs due to group-velocity dispersion (GVD), also called intramodal dispersion or fiber dispersion, which arises because different spectral components of a pulse travel at slightly different velocities.

Types of Intramodal Dispersion

Material Dispersion: This occurs because the refractive index of the fiber material varies with wavelength, causing different frequency components of light to propagate at different speeds. Waveguide Dispersion: This arises from the frequency dependence of the propagation constant for the fundamental mode, influenced by the fiber's core and cladding geometry. The combination of these two effects determines the overall chromatic dispersion of the fiber.

The dispersion can be characterized by the dispersion parameter D, typically expressed in ps/(nm·km), which quantifies the pulse broadening per unit wavelength range and fiber length. Positive D indicates anomalous dispersion (higher frequencies travel faster), while negative D indicates normal dispersion (lower frequencies travel faster).

Wavelength Dependence

In standard single-mode fibers (ITU-T G. 652), dispersion is minimal around 1310 nm, often approaching zero, and increases at longer wavelengths, such as 1550 nm, where it can reach approximately 20 ps/(nm·km),. Specialized fibers, such as dispersion-shifted (DSF) or non-zero dispersion-shifted fibers (NZDSF), are designed to control dispersion for long-haul or dense wavelength-division multiplexing (DWDM) systems.

Impact on Optical CommunicationEven though single-mode fibers avoid intermodal distortion, chromatic dispersion limits the bandwidth and maximum transmission distance. Pulse spreading due to dispersion can reduce signal fidelity, especially in high-speed or long-distance systems, necessitating the use of dispersion compensation techniques or specially designed fibers. In summary, single-mode fiber dispersion is dominated by intramodal effects, specifically material and waveguide dispersion, which together define the chromatic dispersion that governs pulse broadening and system performance.

2.4.2 Dispersion in single-mode fibre

This type of fibre is known as dispersion-shifted fibre (DSF), and the ITU-T have specified such a fibre in recommendation G.653. Instead of avoiding dispersion with low-dispersion fibre, it is possible instead

Single-mode optical fiber

Unlike multi-mode optical fiber, single-mode fiber does not exhibit modal dispersion. This is due to the fiber having such a small cross section that only the first mode is transported.
